ABSTRACT

Objective Effective treatment methods for diabetic peripheral neuropathy are still lacking. Here, a focused ultrasound (FUS) technique was developed to improve blood flow in diabetic peripheral vessels and potentially treat diabetic peripheral neuropathy.

Research design and methods Male adult Sprague-Dawley rats at 4 weeks poststreptozotocin injections were adopted as models for diabetic neuropathic rats. For single FUS treatment, blood perfusion in the skin of the pad of the middle toe was measured before, during, and after the medial and lateral plantar arteries were treated by FUS. For multiple FUS treatments, blood perfusion measurements, von Frey and hot plate testing and nerve conduction velocity measurements were performed before ultrasonic treatment on the first day of each week, and the microvascular and neural fiber densities in the pad of the toe were measured on the first day of the last week.

Results The blood perfusion rate significantly increased for 7–10 min in the control and neuropathic rats after a single ultrasound exposure. Multiple ultrasound treatments compared with no treatments significantly increased blood perfusion at the second week and further enhanced perfusion at the third week in the neuropathic rats. Additionally, the paw withdrawal force and latency significantly increased from 34.33±4.55 g and 3.96±0.25 s at the first week to 39.10±5.02 g and 4.77±0.71 s at the second week and to 41.13±2.57 g and 5.24±0.86 s at the third week, respectively. The low nerve conduction velocity in the diabetic rats also improved after the ultrasound treatments. Additionally, ultrasound treatments halted the decrease in microvessel and neural fiber densities in the skin of the diabetic toes. Histologic analysis indicated no damage to the treated arteries or neighboring tissue.

Conclusions FUS treatment can increase upstream arterial blood flow in diabetic feet, ameliorate the decrease in downstream microvessel perfusion and halt neuropathic progression.

INTRODUCTION

The global prevalence and incidence of diabetes mellitus were 437–522 million and 21–25 million, respectively, in 2017.¹ Over 50% of patients with diabetes can develop diabetic peripheral neuropathy,^{2–3} and the most common presentation is distal symmetric polyneuropathy (DSP).⁴ Patients with diabetic DSP often suffer from pain, numbness or

Significance of this study

What is already known about this subject?

- A vicious cycle between hyperglycemia and microvascular dysfunction can worsen diabetic peripheral neuropathy, particularly distal symmetric polyneuropathy.
- Effective treatment options for diabetic peripheral neuropathy are still lacking.

What are the new findings?

- Focused ultrasound (FUS) treatment on plantar vessels significantly improves diabetic microcirculation.
- FUS therapy concurrently halts diabetes-evoked mechanical allodynic and heat hyperalgesic progression.
- FUS therapy also halts the decrease in the capillary and neural fiber densities in the skin of the pad of diabetic toes.

How might these results change the focus of research or clinical practice?

- Non-invasive FUS treatment potentiates the alleviation of neuropathic pain and/or the prevention of diabetic foot ulcers.

weakness, and some patients even suffer from anxiety, sleep disturbances or foot ulceration and subsequent amputation, leading to a significantly negative impact on their quality of life and an economic burden.^{5–7} Good glycemic control only halts the development of neuropathy in patients with type 1 diabetes and does not affect that of neuropathy in patients with type 2 diabetes.^{8–10} Pain relief can treat symptoms but does not cure DSP.¹¹ Medications based on pathogenetic therapies, such as α -lipoic acid, benfotiamine, aldose-reductase inhibitors, protein kinase C inhibitors, nerve growth factors and Acto-vegin, have been evaluated in clinical trials.¹² However, none of the medications have been approved by the US Food and Drug Administration or European Medicines Agency.

Focused ultrasound (FUS) is a non-invasive, localized, non-ionizing radiation treatment that has been clinically approved to treat

brain disorders.^{13 14} Our previous preclinical studies on diabetic peripheral neuropathy demonstrated that FUS acutely and temporarily blocks the conduction of in vitro sural nerves¹⁵ and compound muscle action potentials of in vivo sciatic nerves in rats with diabetic neuropathy in pain relief applications.¹⁶ To develop a novel and effective method of treating diabetic DSP, the present study investigated the effects of FUS on nerve-accompanying blood vessels and examined the feasibility of curing DSP in neuropathic rats. We hypothesized that: (1) the perfusion rate of downstream blood vessels can be enhanced when FUS acts on upstream arteries, (2) the improvement of perfusion is applicable to both normal and neuropathic nerves and (3) the improvement in perfusion can partially restore sensory normality and halt DSP progression. Blood perfusion in the pad of the middle toe was analyzed before and after the plantar vessels were exposed to ultrasound. Additionally, the chronic effects of FUS on the blood perfusion, paw withdrawal force, withdrawal latency, nerve conduction velocity, skin microvascular density and neural fiber density of sham and DSP rats were examined.

METHODS

Animal subjects

All animal procedures were approved by the Institutional Animal Care and Use Committee of the National Health Research Institutes in Taiwan (AAALAC accredited). Diabetes was induced in male adult Sprague–Dawley

rats weighing 300–400 g by a single intraperitoneal injection of 50 mg/kg streptozotocin (STZ; Sigma, St. Louis, Missouri, USA). The onset of diabetes was defined as three consecutive measurements of a fasting blood glucose level of >150 mg/dL after the STZ injections. The rats exhibited peripheral neuropathy at the fourth week after the STZ injections (online supplementary figure 2).¹⁷

FUS transducer

A tailor-made FUS transducer (figure 1A) was used on the plantar arteries of the rats. The transducer was a 2 MHz spherical bowl with a radius of curvature of 16 mm and an aperture of 20 mm. The front end of the transducer was a hollow cone coupler, and the cone was filled with degassed water and sealed with a 0.03 mm thick Mylar film. The ellipsoidal focus of the transducer was located at a site 5 mm beneath the Mylar film, and the focal width and depth were 0.6 mm and 2.4 mm, respectively. The transducer was driven by a function generator (33 521A, Agilent, Santa Clara, California, USA) and a power amplifier (1040 L, Electronics and Innovation, Rochester, New York, USA) in all experiments.

Measurements of blood perfusion

The rats were anesthetized by the inhalation of isoflurane (3%–4% for induction and 1.25%–1.75% for maintenance, Panion & BF Biotech Inc, Taoyuan, Taiwan) in an oxygen mixture. The anesthetized rats were placed on a custom-made table in the ventral recumbent position,

Figure 1 The experimental setup and design. (A) A custom-made focused ultrasound transducer consisting of a spherically piezoelectrical ceramic, an acrylic cone coupler, housing, electrical connections and circuits was made. (B) The plantar artery of the anesthetized rat was treated by focused ultrasound, and the blood perfusion in the skin of the pad of the middle toe was measured by the laser Doppler instrument. (C) The drawing depicts the locations of the locally treated arteries. The mark on the skin of the sole was the contact point of the ultrasound transducer. (D) For multiple ultrasound treatments, ultrasound exposure was carried out once a day for the first 5 days per week for 2 weeks. Blood perfusion measurements from the end of the middle toe and von Frey testing were performed before ultrasonic treatment on the first day of each week. The microvascular density of the skin on the end of the toe was measured on the first day of the third week. FUS, focused ultrasound.

and both feet were suspended off of the table. The soles of the feet were facing outward, and the five toes of each foot were fixed with tape. The probe (diameter of 0.5 mm, TSD145) of the laser Doppler flowmeter (LDF100c, Biopac Systems, Inc, Goleta, California, USA) was placed so that it gently touched the skin of the pad of the middle toe and blood perfusion could be measured (figure 1B). The data were acquired by the system (Biopac Systems, Inc) at a sampling rate of 200 Hz. Laser Doppler signals from the vessel were recorded in blood perfusion units (BPU's).

Single FUS treatment

The rats (n=12) were randomly divided into two groups: the Control I rats, which received no STZ injections (n=6), and DSP I rats, which received an STZ injection 4 weeks prior (n=6). The light penetrated the rat foot from the instep to the sole so that the medial plantar and lateral plantar arteries were visualized, and two marks that were projected to the two arteries were made on the skin of the sole to position the FUS transducer. The distance between the mark and the ankle was approximately 1.3 cm in all experiments (figure 1C). Ultrasonic gel spread on the skin was used as the acoustic medium, and the medial and lateral plantar arteries were treated once with FUS. Before each plantar artery was treated, the blood perfusion in the end of the middle toe was measured for 60 s as the baseline. For both groups, the left and right feet of every rat were treated sequentially using the same protocol. Ultrasound with a spatial-average temporal-average intensity of 1126 W/cm² and sonication of 15 s was used in each treatment. FUS with the above parameters can cause a temperature increase by 2°C in the focus area in the muscle-mimicking phantom (online supplementary figure 1).

Multiple FUS treatments

The remaining rats (n=12) were randomly divided into two groups: control II rats, which received no STZ injections (n=6), and DSP II rats, which received an STZ injection 4 weeks previously (n=6). The same anesthesia, positioning, equipment and ultrasonic parameters as those described for the single FUS treatment were used. For the DSP II rats, FUS heated the medial plantar artery of the right foot once and then the lateral plantar artery once with an interval of 5 min (DSP II+FUS group), and the left foot of the same rat was regarded as the DSP II sham group. The FUS treatment was carried out once a day for the first 5 days per week for 2 weeks. Blood perfusion measurements in the pad of the middle toe, pain assays and nerve conduction velocity measurements were performed before ultrasonic treatment on the first day of each week, and the microvascular density and the neural fiber density of the toe end skin were measured on the first day of the third week (figure 1D). For the control II rats, the experimental procedure was the same as that for the DSP II sham group.

Neuropathic pain assays

Mechanical allodynia and heat hyperalgesia are usually used as neuropathic indicators and assessed with the von Frey test and hot plate test, respectively.¹⁷ Accordingly, the DSP of the rats that were administered multiple FUS treatments was evaluated using an electronic von Frey device (IITC 2390, IITC Life Science, Woodland Hills, USA) and a hot plate analgesia meter (IITC Life Science) in the present study. The plantar surface of the rat hind paw was stimulated with a rigid tip that was 0.8 mm in diameter. The force was increased gradually until the rat withdrew its paw, and the von Frey anesthesiometer was used to record the withdrawal force. To acclimatize them to the environment, the rats were placed on the hot plate at a temperature of 24±0.5°C for 10 min before the experiment. Each rat was then removed and placed back on the hot plate when the plate was heated to and maintained at 55±0.5°C. The rats expressed distinct behaviors, such as licking the hind paw or abnormally flicking the hind paw, when they felt pain. The withdrawal latency was defined as the time to withdrawal. Five measurements of the withdrawal force and the withdrawal latency were repeated for each rat.

Nerve conduction velocity

The compound nerve action potential of the plantar nerve was recorded with a pair of stainless-steel acupuncture needle electrodes. The anodic recording electrode was inserted at the ankle behind the medial malleolus, and the cathodic electrode was placed 1 cm proximal to the anodic electrode.¹⁸ Two ring silver wires (UL1423 28 AWG B28-1000, AA electronic Test, USA) were placed on the middle three digits as stimulating electrodes to deliver an electrical stimulus with a pulse width of 0.1 ms and a supramaximal intensity. Nerve stimulation and recording were performed using the Biopac MP36 instrument (Biopac Systems, Inc). The nerve conduction velocity was calculated as the distance divided by the latency of the negative peak of the compound action potentials, where the distance between the cathodic stimulating and anodic recording electrodes was measured with a Vernier caliper.

Intraepidermal microvascular density and nerve fiber density

The rats were sacrificed by CO₂ inhalation under anesthesia at the end of the single or multiple FUS treatments. Epidermis-to-dermis tissues from the pads of the second, middle and fourth toes were harvested, fixed in 10% formalin and embedded in paraffin for immunohistochemical staining. The primary antibody of monoclonal anti-CD34 antibody (ab81289, Abcam, Cambridge, Massachusetts, USA) prepared at a 1/200 dilution for 1 hour at room temperature and the secondary antibody of Discovery OmniMap anti-Rb HRP (760-4311, Ventana Medical Systems, Tucson, Arizona, USA) with an ultra-View universal DAB detection kit (760-500, Ventana Medical Systems) were used to stain the vascular endothelial cells brown. The primary and secondary antibodies

used to stain the neural fibers brown were the monoclonal anti-PGP9.5 antibody (ab8189, Abcam) prepared at a 1/1000 dilution for 1 hour at room temperature and Discovery OmniMap anti-Rb HRP with an ultraView universal DAB detection kit, respectively.¹⁹ The endothelial cells and fibers were stained by the Pathology Core Laboratory at the National Health Research Institutes. The tissue sections were scanned at magnifications of 100× to identify the most vascular regions in the dermis. Within these regions, 10 fields (0.0336 mm² per field) were inspected, and immunolabeled microvessels were counted in a 400× field.²⁰ ImageJ software (1.50i, National Institutes of Health, USA) was used to automatically select and count the brown microvessels by setting the color threshold hue to 60 and analyzing particles with sizes >30 μm².²¹ For the nerve fiber density, microphotographs of the stained sections were taken on a microscope at 40× magnification, and the length of the epidermis was assessed with ImageJ software. The intraepidermal nerve fiber profiles were counted by three independent researchers blinded to the study groups.

Histology

Histological analysis was performed to examine the safety of the FUS dose used in the present study. The rats were sacrificed by CO₂ inhalation under anesthesia after 2 weeks of FUS exposure. The tissue treated by FUS was harvested, fixed in 10% formalin and then stained with H&E by a technician blinded to the treatments of the rats.

Statistical analyses

All experimental data are expressed as the mean±SD. When data demonstrated a normal distribution, one-way analysis of variance followed by Duncan's test for post hoc comparisons was used for analysis. Otherwise, non-parametric analysis using the Kruskal-Wallis test and Mann-Whitney U test for post hoc paired comparisons was performed. The levels of statistical significance was set to be **p*<0.05 and ***p*<0.01.

RESULTS

Changes in microcirculation

The blood perfusion in the ends of the right and left middle toes in the DSP I rats (255±48 BPU) was significantly lower than that in the control I rats (479±26 BPU) before single FUS treatment (online supplementary figure 3). Online supplementary figure 3 illustrates one example of a skin blood perfusion profile for a DSP I rat subjected to single ultrasound treatment. The baseline blood perfusion level and the duration of increased perfusion (T) were 203±38 BPU and 144 s, respectively. One FUS sonication to the lateral plantar arteries in the control I rats or DSP I rats resulted in a significant increase in blood perfusion in the ends of the middle toes (figure 2A), where the blood perfusion was increased from 523±51 to 1070±346 BPU for the control I rats and from 255±53 to 890±312 BPU for the DSP I rats. Similar

Figure 2 The microvascular blood perfusion response in the skin of the toe to a single ultrasound exposure on plantar arteries. (A) Skin blood perfusion increased significantly after the lateral plantar artery (LPA) or medial plantar artery (MPA) was treated by ultrasound in the control and DSP rats. Figure 3 Effect of multiple ultrasound treatments on plantar arteries on mechanical allodynia (A) and heat hyperalgesia (B). For the control rats, the paw withdrawal force and latency did not vary significantly over 2 weeks. The withdrawal force and latency of the DSP rats were remarkably low compared with those of the control rats. One-week multiple ultrasound treatments in the DSP rats (DSP II+FUS group) led to a significant increase in the withdrawal force and latency compared with the untreated DSP rats (DSP II sham group). Two-week ultrasound treatments further improved the withdrawal response and latency. Blank bar=first week; slash bar=second week; black bar=third week. * $P<0.05$; ** $p<0.01$. DSP, distal symmetric polyneuropathy; FUS, focused ultrasound.

phenomena occurred for the medial plantar arteries. The perfusion increased significantly from 502 ± 69 BPU and 259 ± 58 BPU at baseline to 1088 ± 278 BPU and 872 ± 317 BPU for the control I rats and DSP I rats, respectively, after single FUS treatment. In addition, increased skin blood perfusion lasted 586 ± 243 s and 429 ± 270 s in the lateral and medial plantar arteries, respectively, of the control I rats and 464 ± 418 s and 411 ± 296 s in the lateral and medial plantar arteries, respectively, of the DSP I rats (figure 2B). Differences in the duration between the above four cases were not significant.

For multiple FUS treatments, blood perfusion in the ends of the middle toes in the DSP II sham group and DSP II+FUS group were 242 ± 36 BPU and 266 ± 45 BPU, respectively, at the first week before FUS treatment (figure 2C). After multiple treatments, the perfusion of the DSP II+FUS group increased significantly to 323 ± 21 BPU at the second week and additionally increased to 360 ± 47 BPU at the third week compared with those of the DSP II sham group. For the DSP II sham group, the perfusion decreased with time but did not change significantly in the 2 weeks. For the DSP II+FUS group, the perfusion of the third week was significantly larger than that of the first week but still lower than that of the control II group (493 ± 26 BPU at the first week, 500 ± 37 BPU at the second week and 492 ± 61 BPU at the third week).

Change in mechanical allodynia and heat hyperalgesia

The paw withdrawal force of the DSP II sham group (33.20 ± 3.13 g at the first week, 31.79 ± 3.18 g at the second week and 28.45 ± 3.39 g at the third week) was significantly lower than that of the control II group (46.59 ± 1.71 g, 46.98 ± 4.04 g and 48.06 ± 2.16 g) (figure 3A). For the DSP II+FUS group, the paw withdrawal force significantly increased from 34.33 ± 4.55 g at the first week to 39.10 ± 5.02

g at the second week and to 41.13 ± 2.57 g at the third week. Furthermore, the third week withdrawal force of the DSP II+FUS group was significantly higher than that of the DSP II sham group and was similar to that of the control II group. The paw withdrawal latency and the paw withdrawal force had similar trends in the control II, DSP II sham and DSP II+FUS groups (figure 3B). The paw withdrawal latency of the DSP II sham group (4.12 ± 0.35 s at the first week, 3.75 ± 0.22 s at the second week and 3.77 ± 0.33 s at the third week) was significantly lower than that of the control II group (4.96 ± 0.27 s, 5.60 ± 0.31 s and 5.19 ± 0.47 s). The paw withdrawal latency

Figure 4 Effect of multiple ultrasound treatments on plantar arteries on plantar nerve conduction velocity. The nerve conduction velocity of the DSP rats was significantly lower than that of the control rats. The velocity of the DSP rats (DSP II+FUS group) increased after multiple ultrasound treatments, whereas the untreated DSP rats had a nearly constant velocity over 2 weeks. Orange circle=control II group; blue square=DSP II sham group; pink triangle=DSP II+FUS group. * $P<0.05$. DSP, distal symmetric polyneuropathy; FUS, focused ultrasound.

Figure 5 Analysis of microvessel density and nerve fiber density in three-toe skin. The two representative pictures of immunostained skin illustrate brown vascular endothelial cells (A) and neural fibers (B). The brown area $>30 \mu\text{m}^2$ denotes a microvessel. Arrows: neural fiber; +: epidermis; #: dermis. (C) The skin microvascular density of all the DSP rats was significantly lower than that of the control rats. Among the DSP rats, the rats at 6 weeks after the STZ injection (DSP II sham group) had a low density compared with the rats at 4 weeks after the STZ injection (DSP I group), but the 6-week rat subjected to a 2-week ultrasound treatment (DSP II+FUS group) had a similar density to the 4-week rats. (D) The nerve fiber density of the DSP I, DSP II sham and DSP II+FUS groups was significantly lower than that of the control II group. Among the DSP I, DSP II sham and DSP II+FUS groups, the DSP II+FUS group had the highest density. * $P<0.05$; ** $p<0.01$. DSP, distal symmetric polyneuropathy; FUS, focused ultrasound; STZ, streptozotocin.

of the DSP II+FUS significantly increased from 3.96 ± 0.25 s at the first week to 4.77 ± 0.71 s at the second week and to 5.24 ± 0.86 s at the third week. Furthermore, the third week withdrawal latency of the DSP II+FUS group was significantly higher than that of the DSP II sham group and was almost the same as that of the control II group.

Change in nerve conduction velocity

The nerve conduction velocity of the DSP II sham group (38.39 ± 1.08 m/s at the first week, 38.16 ± 1.77 m/s at the second week and 38.82 ± 1.43 m/s at the third week) and DSP II+FUS group (38.75 ± 1.53 m/s, 39.92 ± 1.59 m/s and 41.33 ± 2.79 m/s) was significantly lower than that of the control II group (43.44 ± 1.01 m/s, 44.13 ± 1.15 m/s and 45.28 ± 0.89 m/s) (figure 4). The velocity of the DSP II+FUS group gradually increased with time and was higher than that of the DSP II sham group.

Change in skin microvessel density and nerve fiber density

Immunostaining turned the vascular endothelial cells and neural fibers brown, as shown in figure 5A and B. The numbers of microvessels in the skin of the middle three toes were 37 ± 6 , 22 ± 4 , 18 ± 5 and 24 ± 4 per field for the control II group (6-week rats without STZ injection), the DSP I group (4-week STZ rats treated by single FUS), the DSP II sham group (6-week STZ rats) and the DSP II+FUS group (4-week STZ rats treated by the following 2-week FUS), respectively. Compared with the control II group, the DSP I, DSP II sham and DSP II+FUS

groups had significantly lower microvascular density (figure 5C). In addition, the density of the DSP II+FUS group was significantly higher than that of the DSP II sham group and similar to that of DSP I rats. For the nerve fiber density, the epidermal length of the three-toe skin sample was 2.8 ± 0.1 mm, and the number of fibers were 35 ± 12 , 17 ± 2 , 15 ± 3 and 19 ± 5 per mm for the control II group, the DSP I group, the DSP II sham group and the DSP II+FUS group, respectively (figure 5D). The nerve fiber density of the DSP I, DSP II sham and DSP II+FUS groups was significantly lower than that of the control II group. Among the DSP I, DSP II sham and DSP II+FUS groups, the DSP II+FUS group had a highest density.

Staining of the treated tissues

Histological analysis revealed that the morphology of the skin and lateral plantar tissue in the DSP II+FUS rats (figure 6E and F) was similar to that in the DSP II sham rats (figure 6A and B). The treated lateral plantar artery and the neighboring lateral plantar nerve continued to display an organized structure (figure 6F-1 and F-2) similar to that of the untreated artery and nerve (figure 6B-1 and B-2). Similarly, the histological morphology of the skin, medial plantar tissue, medial plantar artery and nerve in the DSP II+FUS rats (figure 6G, H, H-1 and H-2) resembled that in the DSP II sham rats (figure 6C, D, D-1 and D-2). Because the distal medial plantar tissue was

Figure 6 H&E staining images of rat foot tissue cut in the sagittal plane. Figure parts A–D show the skin above the lateral plantar tissue, lateral plantar tissue, skin above the medial plantar tissue and medial plantar tissue of a DSP rat that did not undergo multiple ultrasound treatments. harvested, the medial plantar nerve branches are shown in [figure 6H](#).

DISCUSSION

Human studies have shown that the disruption of skin microvascular blood flow may be an early manifestation of diabetic autonomic neuropathy,^{22–23} and skin vasomotor function is significantly attenuated in patients with diabetic peripheral or autonomic neuropathy.^{24–25} Moreover, nociceptive C fibers secrete substance P to cause vasodilation,^{26–27} and this vasodilation response is decreased in the presence of sensory diabetic neuropathy.^{28–29} Accordingly, skin blood perfusion, in addition to mechanical allodynia, heat hyperalgesia and nerve conduction velocity, was adopted as an indicator of DSP assessment.

Acute effectiveness of FUS in improving the skin blood perfusion of the toe was observed in the control and DSP rats when ultrasound was applied to the plantar artery. The increased level of blood perfusion was twofold that at baseline in the control rats and more than threefold that at baseline in the DSP rats after the single FUS treatment. The phenomenon of increased blood perfusion

lasted 7–10 min in the control and DSP rats. The lateral and medial plantar arteries connect to four common plantar digital arteries and separate into the proper digital arteries for two adjacent toes.^{30–31} Increasing the upstream blood flow probably increases the skin blood perfusion of the middle toe. Therefore, the remarkable results support our assumptions that exposing the upstream arteries to ultrasound can enhance the blood perfusion of downstream or distal small arteries in the toes, and the improvement in perfusion is applicable to both normal and neuropathic nerves. Notably, FUS enables a large increase in perfusion for DSP rats.

Local hyperthermia is one mechanism of increasing blood flow accompanied by the dilation of vessels in normal femoral arteries.^{32–34} These studies have revealed that the temperature increases were 2°C and 1°C in the vastus lateralis muscle and the femoral vein, respectively. Our study showed that FUS induced an increase in temperature by 2°C in the muscle phantom, suggesting local heating in the muscles near the plantar arteries. An estimated increase by 1°C in the plantar artery locally exposed to FUS is plausible. In addition, the mechanical effect induced by ultrasound is probably another

mechanism of vasodilation of the artery.³⁵ Ultrasonic pressure waves may stimulate the vascular endothelium to release vasodilator substances such as nitric oxide and prostacyclin, leading to vascular smooth muscle relaxation and vasodilation.³⁶ Therefore, the synergy of the thermal and mechanical effects of ultrasound contributes to an increase in the blood flow of plantar arteries.

The chronic effects of FUS significantly ameliorated peripheral micro blood perfusion in DSP rats after the first week of treatment, and further improvement was observed after the 2-week treatment. With respect to mechanical allodynia pain and heat hyperalgesia, a similar phenomenon occurred; that is, after the first week of FUS treatment, the paw withdrawal force and latency of the DSP rats markedly increased, and their paw withdrawal force and latency increased further compared with those of the untreated DSP rats after another week of treatment. Notably, the paw withdrawal force and latency of the DSP II+FUS rats were similar to those of the control II rats by the third week. Vascular impairment and metabolic deficits may be major pathogenetic mechanisms responsible for diabetic neuropathy.^{37,38} In cases of diabetes mellitus, autonomic nerve endings to the epineurial arteriole are likely to be lost, and thus, vasoregulation is impaired in the peripheral nerves.³⁹ Impaired autoregulation can cause decreased blood perfusion in transperineurial arterioles and endoneurial capillaries, leading to endoneurial hypoxia and diabetic neuropathy.^{37,40} We presume that FUS-enhanced blood flow increases the vascular supply to the endoneurium and nerve fibers through transperineurial arterioles and endoneurial capillaries and further repairs impaired nerve fibers. The improvement in neural function, which breaks the vicious cycle between decreased local blood perfusion and impaired neural regulatory function, may have synergistic beneficial effects.

Most human studies have shown no significant reduction in skin capillary density in patients with early-stage diabetes.^{41,42} However, capillary loss may eventually occur in the late stage and manifest as diabetic feet. Interestingly, the skin vessel density significantly decreased in the DSP rat models of the present study in the early stage. Furthermore, we found that 2-week FUS treatments can halt the decrease in the number of microvessels in the DSP rats. Growing evidence shows a vicious cycle of hyperglycemia and microvascular dysfunction.⁴³ Hyperglycemia induces microvascular dysfunction, such as a reduced capillary density in muscle, and microvascular dysfunction reduces glucose disposal in muscle and insulin secretion by pancreatic islets, leading to hyperglycemia. Our study demonstrated that FUS treatment of peripheral vessels can enhance blood flow and halt the decrease in capillary density, which may improve cases of hyperglycemia and DSP.

A decrease in the plantar nerve conduction velocity was also ameliorated in the diabetic rats treated with FUS. Diabetes elicits functional and structural changes in the peripheral nerve, decreasing the nerve conduction

velocity. Two-week FUS treatments on the peripheral blood vessel may halt the reduction in nodal or paranodal potassium currents in neural axons⁴⁴ and even arrest the reduction in myelin sheath surface area, myelin/axon ratio and the number of unmyelinated axons or small fibers⁴⁵ due to improved microcirculation of blood, which increases the low conduction velocity.

The thermal dose that caused damage to 50% of the vessels was 144 ± 46 equivalent minutes at 43°C for the normal vessels,⁴⁶ and the thermal dose of heat-induced cell death was 210–240 min for muscle, fat and skin.⁴⁷ The thermal dose of the plantar vessel induced by FUS (15 s at body temperature $+2^\circ\text{C}$) is much lower than the above thermal dose of vessel damage. Moreover, the histological analysis shows the undisrupted morphology of the skin, fat, muscle and vessels treated by FUS. Therefore, the FUS parameters used in the study did not cause adverse biological effects.

Rats with short-term diabetes mainly develop pain, whereas those with longer term diabetes typically develop both pain and insensate symptoms.⁶ Hypoalgesia was not evaluated because we believe interventions may be more effective in the early state of neuropathy before irreversible changes appear. Although numbness and hypoaesthesia were the major initial symptoms of distal symmetric diabetic polyneuropathy in humans, microangiopathy was the major underlying etiology, similar to that in STZ-induced rats. Because improvements in blood perfusion and the number of microvessels and neural fibers were shown in this study, the difference in the initial presentation of neural dysfunction in the animal model may not hinder the contribution of the present study.

We have developed the first FUS technique for modulating diabetic blood vessels and demonstrated that increasing the blood flow of upstream plantar vessels can increase the downstream microcirculation in the skin of toes. Additionally, we showed that allodynic and hyperalgesic pain improve after FUS treatments and that the increases in paw withdrawal force and latency are positively correlated with the increase in the perfusion rate of the skin vessels. FUS treatment also halts the decreases in microvessel density and neural fiber density in the skin of diabetic feet. These findings corroborate the FUS treatment efficacy for diabetic distal polyneuropathy.

Acknowledgements The authors would like to thank the Pathology Core Laboratory of the National Health Research Institutes for the staining work performed in the study.

Contributors J-ST performed the experiments and statistical analyses and drafted the manuscript. C-CL contributed to the discussion and reviewed the manuscript. G-SC designed the study, contributed to the discussion and reviewed/edited the manuscript. G-SC is the guarantor of this work and, as such, had full access to all data in the study and takes responsibility for the integrity and accuracy of the data analysis.

Funding This work was supported by the National Health Research Institutes (BN-108-PP-10) and the Ministry of Science and Technology (MOST 105-2221-E-400-004-MY3 and MOST 108-2221-E-400-001) in Taiwan.

Competing interests None declared.

Patient consent for publication Not required.

Ethics approval All animal procedures were approved by the Institutional Animal Care and Use Committee of the National Health Research Institutes in Taiwan (AAALAC accredited).

Provenance and peer review Not commissioned; externally peer reviewed.

Data availability statement All data relevant to the study are included in the article or uploaded as supplementary information.
