ABSTRACT

Introduction Compared with many other countries Russia has a high prevalence of diabetes in men and women. However, contrary to what is found in most other populations, the risk is greater among women than men. The reasons for this are unclear.

Research design and methods Prevalence and risk factors for diabetes at ages 40–69 years were compared in two population-based studies: Know Your Heart (KYH) (Russia, 2015–2018, n=4121) and the seventh wave of the Tromsø Study (Tromsø 7) (Norway, 2015–2016, n=17 649). Diabetes was defined by the level of glycated hemoglobin and/or self-reported diabetes and/or diabetes medication use. Marginal structural models were used to estimate the role of key risk factors for diabetes in differences between the studies.

Results Age-standardized prevalence of diabetes was higher in KYH compared with Tromsø 7 in men (11.6% vs 6.2%) and in women (13.2% vs 4.3%). Age-adjusted ORs for diabetes in KYH compared with Tromsø 7 were 2.01 (95% CI 1.68 to 2.40) for men and 3.66 (95% CI 3.13 to 4.26) for women. Adiposity (body mass index and waist circumference) explained none of this effect for men but explained 46.0% (39.6, 53.8) for women. Addition of smoking and C reactive protein, as further mediators, slightly increased the percentage explained of the difference between studies to 55.5% (46.5, 66.0) for women but only to 9.9% (–0.6, 20.8) for men.

Conclusions Adiposity is a key modifiable risk factor that appears to explain half of the almost threefold higher female prevalence of diabetes in Russia compared with Norway, but none of the twofold male difference.

INTRODUCTION

Diabetes has an independent effect on the risk of cardiovascular events¹ and causes long-term microvascular complications.^{2–3} The disease is heterogeneous in nature and progression and is broadly classified into type 1 diabetes and type 2 diabetes.⁴ Type 2 diabetes is strongly associated with obesity and related lifestyle factors and is the most common type in adults.⁴

Significance of this study

What is already known about this subject?

- Russia has strikingly higher diabetes rates compared with Western countries occurring within the context of a very high mortality from cardiovascular disease and low life expectancy at birth.
- Unlike many other countries diabetes is more common among women than men at older ages.

What are the new findings?

- Obesity and measures of adiposity contribute substantially to the higher prevalence of diabetes among women in Russia compared with women in Norway; however, obesity did not explain differences in diabetes prevalence among men between the two countries.
- Even after accounting for obesity and other risk factors, diabetes prevalence remained a lot higher in the Russian study than in Norway for both sexes.
- The proportion of undiagnosed diabetes in Russia is much higher than in Norway.

How might these results change the focus of research or clinical practice?

- Strategies to reduce levels of adiposity in the Russian population are important, with a need to focus on reducing levels in women.
- The proportion of undiagnosed diabetes in Russia should be reduced by targeted screening efforts.

Population aging and the worldwide rise in obesity have contributed to the marked rise in type 2 diabetes prevalence in many countries, although there remains substantial international variation.⁵ Data on type 2 diabetes prevalence in Russia have been reported in a few population-based studies based either on glycated hemoglobin^{6–8} or fasting glucose.^{9–11} These studies report relatively high prevalence of type 2 diabetes in Russia ranging from 7% to 16%, with the highest burden being in women compared with men at older ages.

The notably higher prevalence in women compared with men is atypical compared with many other countries.^{4 5} The high prevalence of diabetes in Russia compared with the neighboring countries in Western Europe is of particular interest because this may contribute to the very high levels of cardiovascular disease (CVD) in Russia.¹² However, no systematic attempt has been made previously to investigate which risk factors may explain the relatively high prevalence of diabetes in Russia compared with elsewhere.

At early stages symptoms of type 2 diabetes are absent or remain unnoticed; therefore a substantial proportion of type 2 diabetes remain undiagnosed and not managed.¹³ Previous studies in Russia reported a very high proportion of undiagnosed diabetes (up to 54%).⁸ This can lead to delay in management of the condition and health-care interventions directed to reduce cardiometabolic risk factors such as hypercholesterolemia, hypertension, hypoglycemia, and obesity.

In this study we aim to investigate whether high diabetes prevalence in Russia compared with Norway is explained by known risk factors of diabetes. We used data collected in two recent cross-sectional, population-based studies conducted in Russia and Norway that defined diabetes in a comparable manner. These countries share a border and have similar population age structure.

METHODS

Study populations

We used data on men and women aged 40–69 years who took part in two population-based studies. The Know Your Heart (KYH) study¹⁴ is a cross-sectional study conducted in Russia in 2015–2017. The seventh wave of Tromsø Study (Tromsø 7)¹⁵ was conducted among the residents of the municipality of Tromsø (Norway) in 2015–2016.

Know Your Heart (Russia)

A random population-based sample of participants aged 35–69 years old ($n=5071$) stratified by age, sex and district were recruited in Arkhangelsk and Novosibirsk cities (Russia). Trained interviewers visited the sampled addresses and recorded information about residents' health, sociodemographic characteristics and lifestyle (51% of approached agreed to participate). Participants were then invited to take part in a health check that usually occurred 1–2 weeks later in a research clinic and 4512 (35–69 years old) agreed (89%). Our analysis is based on 4121 participants aged 40–69 years who attended the health check (online supplemental figure 1). The health check included a medical examination, questionnaire and biological sample collection. The medical examination included blood pressure measurements and recording of weight and height. The questionnaire collected data on health problems, lifestyle, and medication use. The blood samples were non-fasting, but participants were asked not to eat and drink for 4 hours before the health check. Within 2 hours after venipuncture,

blood samples were centrifuged, and serum was frozen at -80°C . Frozen samples were shipped to a laboratory in Moscow and analyzed in a single batch at the end of the fieldwork. Further details of the study design have been published elsewhere.¹⁴

Tromsø 7 (Norway)

All inhabitants of the municipality of Tromsø aged 40 years and above were invited to take part in Tromsø 7 and 21 083 participated (65%), of whom 17 649 aged 40–69 years were included in our analysis (online supplemental figure 2). All participants completed the questionnaires and examinations including biological sampling. The questionnaire included a broad set of questions on lifestyle, medication use, and disease. Blood samples (non-fasting) were processed immediately after collection and the laboratory assays of the biomarkers were done on the same day at the Department of Laboratory Medicine, University Hospital of Northern Norway (International Organization for Standardization (ISO) certification NS-EN ISO 15189:2012). Further details of the design of the Tromsø Study have been published elsewhere.¹⁵

Outcomes

The outcome of the study is the prevalence of diabetes mellitus, defined as glycated hemoglobin (HbA1c) $>6.5\%$ (48 mmol/mol)¹⁶ and/or self-reported diabetes and/or use of medication for diabetes (online supplemental table 1). Use of medication for diabetes was collected based on answers to the question about diabetes medication use and/or drugs taken during the last 4 weeks coded with A10 (antidiabetics) of the Anatomical Therapeutic Chemical classification.¹⁷ In KYH, diabetes self-report was determined from the question 'Have you ever been told by a doctor or nurse that you have diabetes mellitus?' In Tromsø 7, participants who answered that they currently have diabetes on the question 'Have you or have you ever had diabetes?' were recorded as having diabetes. A person with HbA1c $\geq 6.5\%$ (48 mmol/mol) was considered undiagnosed if they did not report having diabetes or taking diabetes medications. Pre-diabetes was defined as HbA1c $\geq 5.7\%$ (39 mmol/mol) and $<6.5\%$ (48 mmol/mol) among those who did not report that they have diabetes or take diabetes medications.¹⁶

HbA1c was measured in whole blood by immunoturbidimetric test on AU680 Chemistry System (Beckman Coulter) in KYH and by capillary electrophoresis on Capillarys 3 Tera with the MCA Laboratory HbA1c calibrator traceable to the International Federation of Clinical Chemistry reference measurement in Tromsø 7. A calibration study between the two laboratories was conducted and HbA1c levels were adjusted appropriately to make them directly comparable.¹⁸

We were not able to distinguish between type 1 and type 2 diabetes in this study as consistent and comparable data on age at onset and other distinctive characteristics of these two conditions were not available.

Exposure variables

Adiposity was assessed using body mass index (BMI) and waist circumference (WC). WC was measured at the narrowest part of the trunk (KYH) or at the umbilical level (Tromsø 7). To ensure comparability, WC in Tromsø 7 was converted to the narrowest waist using a conversion equation.¹⁹ Mean systolic and diastolic blood pressure were calculated as the mean of the second and third measurements. Smoking was categorized as ex-smokers, never-smokers and current smokers (1–10 cigarettes per day, 11–20 cigarettes per day, >20 cigarettes per day). Total cholesterol, low-density lipoprotein (LDL) cholesterol, high-density lipoprotein cholesterol, triglycerides, and high sensitivity C-reactive protein (hsCRP) were measured.^{14 18} A calibration study of the laboratory biomarkers was conducted to harmonize measurements between studies.¹⁸

All participants gave signed consent.

Statistical analysis

Sex-specific prevalence of diabetes, pre-diabetes, and undiagnosed diabetes in the two studies were compared after age standardization to the Standard European Population 2013.

To examine if the differences in prevalence of diabetes between studies may be explained by different levels of diabetes risk factors, we conducted mediation analysis using marginal structural models,²⁰ which allow the decomposition of total effect of exposure into that

mediated by specific factors (indirect effect) and the remaining (direct) effect. In our analysis, the study (KYH vs Tromsø 7) was considered the exposure, while diabetes risk factors were considered possible mediators. BMI and WC were added together at the first step of the mediation analysis to provide an estimate of the role of adiposity, and the independent effects were not examined.²¹ Both BMI and WC were modeled as quintiles to account for non-linearity of the association by diabetes (online supplemental figures 3 and 4); quintiles were defined based on the total study population of men and women from both studies. A further model introduced smoking and hsCRP as additional mediators, the latter as it reflects proinflammatory status.^{21 22} Mediation analysis was done stratified by sex, and age was treated as a confounder.

Statistical analysis was performed using R V.3.6.0 (package medflex 0.66) and SAS V.9.4.

Sensitivity analysis

Self-report of diabetes diagnosis may not be fully reliable. We therefore conducted a sensitivity analysis for mediation analyses and comparison of CVD risk factor profile where defined diabetes was based on HbA1c values alone.

RESULTS

Age-standardized prevalence of diabetes, pre-diabetes and undiagnosed diabetes was higher in KYH compared with Tromsø 7 among men and women (table 1 and

†Diabetes among participants with measured HbA1c was defined as HbA1c \geq 6.5% (48 mmol/mol) and/or self-reported diabetes and/or use of medication with ATC code A10 (antidiabetics) according to the Anatomical Therapeutic Chemical (ATC) classification.

‡Undiagnosed diabetes among participants with measured HbA1c was defined as HbA1c \geq 6.5% (48 mmol/mol), no self-reported diabetes and no diabetes medication use.
HbA1c, glycosylated hemoglobin.

online supplemental table 1). The proportion of those with diabetes who were undiagnosed was higher in KYH than in Tromsø 7 both in younger and older age groups (table 2).

Next we compared cardiometabolic risk factor profiles among participants with diabetes and without diabetes in both studies (table 3). In both studies men and women with diabetes had higher BMI and WC, higher systolic and diastolic blood pressure, and higher hsCRP levels than those who do not have diabetes. In KYH levels of total and LDL-cholesterol were similar in participants with and without diabetes; however, in Tromsø 7 total and LDL-cholesterol were lower in participants with diabetes. Smoking prevalence was similar in participants with and without diabetes in both studies. Use of lipid-lowering drugs was higher in Tromsø 7 study, in particular among participants with diabetes. Substantial differences in mean risk factor levels were observed between KYH and Tromsø 7. Systolic and diastolic blood pressure were higher in KYH than in Tromsø 7, and smoking prevalence was higher among men and mean BMI and WC were higher among women in KYH compared with Tromsø 7 (online supplemental table 6).

The age-adjusted odds of having diabetes in KYH were twice that in Tromsø 7 among men and more than three times higher among women, as shown by the size of the total effect in table 4. Differences in distribution of BMI and WC did not appear to explain any of the differences in diabetes prevalence between study populations among men. The estimation of natural indirect effect of all mediators considered (BMI, WC, hsCRP, smoking) among men yielded an OR of 1.07 (0.99, 1.16), which indicates a small contribution of mediators to the differences in diabetes prevalence between studies (total effect). This is reflected by a small mediated percentage: 9.9% (−0.6, 20.8). On the contrary, the natural indirect

effect of two measures of adiposity (BMI, WC) among women was estimated from an OR of 1.81 (1.68, 1.94), which corresponds to 46.0% (39.6, 53.8) of the diabetes differences between KYH and Tromsø 7 being explained by these two mediators. With addition of two remaining mediators (hsCRP and smoking), the natural indirect effect slightly increased to OR=2.04 (1.85, 2.26), which corresponds to 55.5% (46.5, 66.0) of the difference in prevalence between studies in women explained by all considered mediators (table 4). It was notable that the residual (natural direct effect) effects not mediated by BMI and WC were similar in men and women.

Sensitivity analysis

The results of the mediation analysis were similar if conducted separately for diagnosed and undiagnosed diabetes (online supplemental tables 4 and 5); however, the contribution of BMI and WC to the mediation was smaller for undiagnosed than diagnosed diabetes.

Sensitivity analysis using a diabetes case definition based solely on HbA1c values did not substantially change the findings of the mediation analysis or of the comparison of the CVD risk factor profile (data available from authors).

DISCUSSION

In this study we compared the prevalence of diabetes in two population-based studies conducted in Russia and Norway using the same case definitions. We found much higher prevalence of diabetes in KYH (11.6% in men and 13.2% in women) compared with Tromsø 7 (6.2% in men and 4.3% in women). The prevalence of diabetes was higher in women than in men in the Russian sample, which is the opposite of what is observed in Norway and other countries.^{4 5} We also found that there is a higher

Natural indirect effect	1.81 (1.68, 1.94)	2.04 (1.85, 2.26)
Total effect	3.66 (3.13, 4.26)	3.62 (3.10, 4.21)
Percentage mediated	46.0% (39.6, 53.8)	55.5% (46.5, 66.0)

*Adjusted for age.

†Total effect of exposure is decomposed into natural direct and indirect effects. Natural indirect effect means effect of exposure that is mediated by a specific set of risk factors. Natural direct effect is the remaining effect of an exposure after quantifying the natural indirect effect. In our analysis, the study (KYH vs Tromsø 7) was considered the exposure, while diabetes risk factors were considered possible mediators.

‡Diabetes defined as HbA1c \geq 6.5% (48 mmol/mol) and/or self-reported diabetes and/or use of medication with ATC code A10 (antidiabetics) according to the Anatomical Therapeutic Chemical (ATC) classification.

BMI, body mass index; HbA1c, glycated hemoglobin; hsCRP, high sensitivity C reactive protein; KYH, Know Your Heart.

proportion of undiagnosed diabetes in Russia than in Norway, with proportions of previously undiagnosed diabetes of 36.9% among men and 26.8% among women in KYH.

We attempted to explain the differences in prevalence of diabetes between the two countries using mediation analysis and found that adiposity measured by BMI and WC could explain up to 46% of the difference in diabetes prevalence between studies in women, but did not explain the differences between studies observed in men. Taking further account of smoking and hsCRP as mediation factors in addition to adiposity could explain 55.5% of the differences in diabetes prevalence between studies in women.

Our estimates of diabetes prevalence in Russia are in line with previous studies, although not all of them are published in the peer review literature or contain sufficient detail on age-specific diabetes prevalence.^{7 10 11 23} Two recent multiregion studies in Russia reported age-specific prevalence of diabetes and found that women at older ages have higher prevalence of diabetes than men.^{8 9} The NATION study (2013–2015) estimated type 2 diabetes prevalence based on both HbA1c and self-report: 7.0% of women vs 7.9% of men aged 45–59 years old and 14.1% of women vs 9.9% of men aged 60–79 years had diabetes.⁸ The ESSE-RF study (10 regions of the Russian Federation, 2012–2014) estimated the prevalence of diabetes mellitus based on self-report and fasting glucose: 9.4% of men and 7.4% of women aged 45–54 years old and 13.6% of men and 16.5% of women aged 55–64 years old had diabetes mellitus.⁹ Similarly to

our study, other studies conducted in Russia report that a high proportion of diabetes is undiagnosed: 54% in NATION study,⁸ 43% in HAPIEE,¹⁰ and 27% in UEMS.¹¹ Differences between these estimates and estimates from our study can be explained by the different age structures of the studied populations, different access to healthcare services in Russian regions, and different methods for diabetes prevalence estimates.

According to the WHO STEPwise approach to surveillance (STEPS) (2019), raised fasting blood glucose (\geq 7.0 mmol/L) or under medication for raised blood glucose was found in 7.1% of the Ukrainian population: 6.7% of men and 7.4% of women (18–69 years old). Nearly half of them had not previously been diagnosed with diabetes.²⁴ The percentage of population with diabetes is lower in Belarus (3.2 of men and 3.9 of women) and higher in the Republic of Moldova (11.5 of men and 13.0 of women); however, in all three countries the prevalence of diabetes in women is higher than in men.²⁵ The higher prevalence of diabetes in women than men observed in KYH is the opposite pattern to that observed in Norway and most other countries where the majority of the population are of European ancestry. The higher diabetes prevalence in men is usually explained by diverse biological, cultural, lifestyle, and environmental factors.^{26–29} Explanations for the pattern observed in Russia require further research. Certain cultural factors in Russia may be considered distal, that is, influencing behavior, and modify the biologically lower predisposition of women to develop diabetes.

Estimates of the prevalence of diabetes in Norway are available from national registries with prospectively collected data on prescriptions of antidiabetic drugs and diabetes diagnoses from hospitals and primary care visits for all residents in Norway aged 30–89 years. Crude prevalence of type 2 diabetes increased from 4.9% to 6.1% from 2009 to 2014, and diabetes prevalence was higher in men than in women (6.8% vs 5.3% in 2014).³⁰ However, these estimates do not include undiagnosed diabetes cases that would be detected by screening. Intensive pharmacological and lifestyle management of diabetes delays onset and slows the progression of diabetes complications.^{31 32} Our study has shown that the proportion of undiagnosed diabetes is apparently smaller in the Norwegian study compared with the Russian study, but is still of significant public health concern given the potential health consequences of unmanaged diabetes.³³

Weight reduction and diet modification interventions in people with impaired glucose tolerance reduced the incidence of diabetes in randomized controlled trials.^{34 35} Therefore, lifestyle interventions would be beneficial for both persons with clinically defined diabetes and persons with pre-diabetes.³⁶ In our study prevalence of pre-diabetes was higher in KYH compared with Tromsø 7, which means there is much potential for diabetes prevention. Incorporation of a broader definition of pre-diabetes (HbA1c $\geq 5.7\%$ or fasting glucose ≥ 5.6 mmol/L) to the diagnosis guidelines in Russia may be justified to prevent more cases of diabetes with timely intervention if the change in cut-points is shown to be cost-effective.

Our data do not explain in full why prevalence of diabetes differs in Norway and Russia particularly among men. Our measures of adiposity (BMI and WC) explained a substantial proportion of difference among women (46%), but these factors did not make an important contribution to differences among men. Interestingly, after accounting for adiposity the remaining difference in diabetes prevalence between KYH and Tromsø 7 study was similar for men and women (double the odds of diabetes prevalence). It was previously shown even among people of European ancestry that differences exist in the relationship between body fat and BMI.³⁷ Also, the association of obesity and diabetes was shown to be stronger in low education groups, which suggests that socioeconomic circumstances may influence vulnerability to adiposity.³⁸

It has been previously demonstrated that smoking is associated with diabetes, with a relative risk of 1.4 (adjusted for the baseline BMI).^{22 39} hsCRP reflects the level of general inflammation and is positively associated with obesity and diabetes.²¹ As the prevalence of smoking and hsCRP levels are higher among Russian men compared with men in Norway, we expected them to contribute to some of the difference in diabetes prevalence. However, we did not observe an additional contribution of these factors to explaining the differences in diabetes prevalence when adiposity measures were already included in the model. Among women, smoking and hsCRP made a small additional contribution to the

difference in diabetes prevalence between studies after accounting for adiposity.

There are other potential explanations for the differences in diabetes prevalence between studies, such as diet,^{40 41} levels of physical activity,⁴² and sedentary behavior.⁴³ Unfortunately, comparable data on these factors between our two studies are not available.

Type 2 diabetes is a multifactorial disease and involves genetic, behavioral and environmental factors, and their interaction.⁴⁴ However, researchers still have a limited understanding of the genetic and epigenetic contribution to type 2 diabetes: only 10%–15% of heritability can be explained by known genetic variants.⁴⁵ At the present time we do not have genomic data for both studies in order to investigate any differences between them.

Limitations

The major limitation of the mediation analysis in our study is the cross-sectional nature of the data. People who knew they had diabetes could have attempted to lose weight, increase physical activity, eat a healthier diet, and stop smoking. For example, lower LDL-cholesterol levels in participants with diabetes in Tromsø 7 study can in part be explained by higher use of lipid-lowering medications and changes in diet after diabetes diagnosis. Beyond this it is likely that our anthropometric measures of adiposity in the two populations failed to adequately capture differences in the extent of visceral abdominal adiposity, which is particularly strongly related to risk of diabetes.⁴⁶ Validity of the mediation estimates is dependent on the assumption of no uncontrolled confounding for the exposure–outcome, exposure–mediator, or mediator–outcome relations.²⁰

Although we were not able to distinguish between type 1 diabetes and type 2 diabetes in our study, our results will be principally driven by type 2 diabetes because it constitutes between 90% and 95% of all diabetes in these populations.⁴

Finally, care must be taken before generalizing the study findings to the populations of Russia and Norway as a whole. First, the studies were conducted in three cities whose characteristics will differ in some respects from the national populations. In addition there is the uncertainty about whether the participants we studied were representative of their own cities' populations. The Tromsø 7 study had a good response rate (65%), as did the study in Arkhangelsk (68%), although in Novosibirsk the response rate was low (41%).¹⁴ The participants who did not attend the health check in KYH study were likely to have more adverse risk factor profile than those who did (online supplemental tables 2 and 3). However it is notable that our estimates of diabetes prevalence from KYH are consistent with those of other population-based studies in Russia. Similarly, prevalence estimates for diabetes in Tromsø 7 are similar to the study reporting diabetes prevalence in the whole of Norway. Potential explanatory (mediating) effects of specific biomedical markers are likely not to be affected.

CONCLUSIONS

The major differences in diabetes prevalence between Russia and Norway have important implications for health services in Russia and could contribute to the differences in CVD mortality between the two countries. Adiposity indices, smoking and C reactive protein only partially explained the differences in diabetes prevalence between studies in women and did not explain differences between diabetes prevalence in men. A substantial proportion of unexplained differences remained and requires further investigation. People with undiagnosed diabetes are not prescribed recommended glucose-lowering, blood pressure-lowering and lipid-lowering drugs, as well as antismoking counseling, which can be expected to reduce the risk of CVD and other complications of diabetes. The proportion of undiagnosed diabetes in Russia is alarmingly high given potential health consequences for individuals and subsequent burden from avoidable complications of diabetes on the healthcare system.

Acknowledgements We would like to acknowledge the contribution of the participants of the KYH study and the Tromsø Study.

Contributors OI and DAL codesigned the study analysis. OI, MA, AVK, TW, SC, AEE, LAH, DAL, SM, and SW made substantial contribution to the acquisition and interpretation of data. OI carried out the data analysis and drafted the manuscript. All authors revised the manuscript critically. All authors contributed to the interpretation of the results and gave final approval of the report to be published. OI accepts full responsibility for the work and/or the conduct of the study, had access to the data, and controlled the decision to publish.

Funding The KYH study is a component of the International Project on Cardiovascular Disease in Russia (IPCDR). IPCDR was funded by the a Wellcome Trust Strategic Award (100217), supported by funds from UiT The Arctic University of Norway; the Norwegian Institute of Public Health; and the Norwegian Ministry of Health and Social Affairs. The seventh wave of the Tromsø Study was funded by the UiT The Arctic University of Norway, Northern Norway Regional Health Authority, Norwegian Ministry of Health and Social Services, and Troms County. SM is supported by the Russian Academy of Sciences, State Target (A.A.A.A.-A17-117112850280-2). DAL was partly supported by the Basic Research Program of the National Research University Higher School of Economics. The study sponsor/funder was not involved in the design of the study; the collection, analysis, and interpretation of data; writing the report; and did not impose any restrictions regarding the publication of the report.

Competing interests None declared.

Patient consent for publication Not required.

Ethics approval Ethical approval for the study was received from the ethics committees of the London School of Hygiene & Tropical Medicine (approval number 8808, February 24, 2015), Novosibirsk State Medical University (approval number 75, May 21, 2015), the Institute of Preventative Medicine (no approval number; December 26, 2014), and Novosibirsk and the Northern State Medical University, Arkhangelsk (approval number 01/01-15, January 27, 2015). The Regional Committee for Research Ethics approved Tromsø 7 (REC North ref 2014/940). Both studies have conformed to the principles embodied in the Declaration of Helsinki.

Provenance and peer review Not commissioned; externally peer reviewed.

Data availability statement Data are available upon reasonable request. Requests to access the data set of KYH study from bona fide researchers may be sent to the International Project on Cardiovascular Disease in Russia: <https://metadata.knowyourheart.science/>. Application for access to Tromsø study data can be sent to tromsous@uit.no.
